Package managers are everywhere, with seemingly every language and operating system implementing their own solution. The lack of interoperability between these systems means that multi-lingual projects are unable to express precise dependencies across language ecosystems, and external system and hardware dependencies are typically implicit and unversioned. We define HyperRes, a formal system for describing versioned dependency resolution using a hypergraph that is expressive enough to model many ecosystems and solve dependency constraints across them. We define translations from dozens of existing package managers to HyperRes and comprehensively demonstrate that dependency resolution can work across ecosystems that are currently distinct. This does not require users to shift their choice of package managers; instead, HyperRes allows for the translation of packaging metadata between ecosystems, and for solving to be precisely specialised to a particular deployment environment.

1 INTRODUCTION

Almost every programmer uses package managers to manage their codebases, but they remain mysteriously ad-hoc and non-interoperable. Package management software originally began with operating system distributions in the 1990s, popularised by Debian, Red Hat and Slackware. These system package managers are responsible for distributing, assembling and managing filesystems which boot a distribution, and they typically focus on binary distributions to their users [42]. A few years on, they were joined by language-specific package managers [45, 54] that sit alongside the system package managers and offer more flexible and domain-specific interfaces to individual language ecosystems. A language package manager typically allows for selecting from multiple versions of a particular library, and for easier source-based compilation of a development branch.

Today, there is an explosion of both system and language package managers, each with seemingly incompatible interfaces. This leads to all sorts of problems when trying to use packages from different ecosystems together. Consider, for example, a project which uses a combination of C, Rust and OCaml code for a static binary, with more dynamic Python bindings that use GPU drivers that depend on a particular kernel driver. Getting these (sometimes interlocked) dependencies resolved and stable is a Herculean task that is difficult to automate and keep reproducible. The complexity led to the rise of containerization technologies like Docker, which sidestep the problem by bundling

Authors' addresses: [Ryan Gibb](#), ryan.gibb@cl.cam.ac.uk, University of Cambridge, United Kingdom; [Patrick Ferris](#), University of Cambridge, United Kingdom; [David Allsopp](#), Tarides, United Kingdom; [Michael Winston Dales](#), University of Cambridge, United Kingdom; [Mark Elvers](#), Tarides, United Kingdom, mte24@cam.ac.uk; [Thomas Gazagnaire](#), Tarides, France, thomas@tarides.com; [Sadiq Jaffer](#), University of Cambridge, United Kingdom, sj514@cam.ac.uk; [Thomas Leonard](#), University of Cambridge, United Kingdom; [Jon Ludlam](#), Tarides, United Kingdom; [Anil Madhavapeddy](#), University of Cambridge, United Kingdom, anil.madhavapeddy@cam.ac.uk.

all dependencies together, but ultimately result in rather brittle deployments which are difficult to manage across ecosystems. In our earlier example, four separate package managers are required to deploy this program: opam, Cargo, pip and APT. If the program is to be portable beyond Debian, then even more will be required (e.g. APK for Alpine, or RPM for Red Hat Linux). Such a project might also break if the kernel GPU driver is updated, or if a Rust library is updated to a version that is incompatible with the particular version of Python used in the machine learning codebases. If a security hole is found in one component, the whole stack must be upgraded very carefully indeed. If continuous integration is deployed against the project, then all the package managers must be carefully managed to keep the deployment reproducible. This situation is unergonomic, error-prone and deeply unsatisfying.

Yet all these package managers share a common core: they all resolve dependencies from a package repository and eventually output a filesystem subtree. In this paper, we present a formal system that teases apart the seemingly monolithic features of package managers across both the operating system and programming language ecosystems, which we call the ‘hypergraph dependency resolution’ (HyperRes) formalism. HyperRes can not only be used to model many real-world package managers, but also forms the basis for the new ability to unify resolution requests across package management ecosystems with a single formula. HyperRes can even be used to bidirectionally translate requirements directly into the package manager native formats, thus simplifying day-to-day management of multi-language and OS-portable software projects. In the longer term, the HyperRes unified approach to version specification is vital towards securing software supply chains that are increasingly targeted by malicious actors.

HyperRes aims to extract a common core expressive enough to model numerous package managers, allowing resolution across their ecosystems. In our earlier example, we would construct a single formula that would resolve OCaml, Python and Rust packages together with the system dependencies already available with a given Linux distribution. HyperRes lifts the insight from earlier work [58] that package managers can be modelled as a constraint satisfaction problem, but extends it to a hypergraph structure that is suitable for bidirectional translation of the resolution formulae between ecosystems. Thus, we can now even mechanically take a complex (e.g.) OCaml/Rust/Python project and create a binary deb package that is binary-compatible with a given version of Debian Linux, by finding the common subset of packages that are already pre-packaged on that distribution vs those that need to be compiled from sources due to being only present in a particular package management ecosystem. Today, this is a laborious and error-prone task that needs to be repeated per-distribution and per-architecture.

In the remainder of this paper, we will first sketch out HyperRes informally (§1.1). We then classify the commonality between many package managers (§2), and define the formal system for reasoning about dependency resolution from a resolution hypergraph to a resolved graph (§3). We show how this system is expressive enough to model many real-world package managers (§4) and how we can use it as the basis to resolve dependencies across package management ecosystems (§5). Finally, we consider related work and directions for future work (§6) and conclude (§7).

1.1 An Illustrated Resolution Hypergraph

We will first begin with a sketch of the HyperRes formalism (§3), with Figure 1 showing an example of a cross-ecosystem package hypergraph. A hypergraph is a generalisation of a graph in which a ‘hyperedge’ can join any number of vertices. The diagram shows a hyperedge-labelled directed hypergraph representing a dependency resolution problem across ecosystems. Vertices in this graph are packages, defined as a pair of package name and package version. The packages included are real, but their relationships are chosen to illustrate interesting scenarios and to omit uninteresting incidental detail.

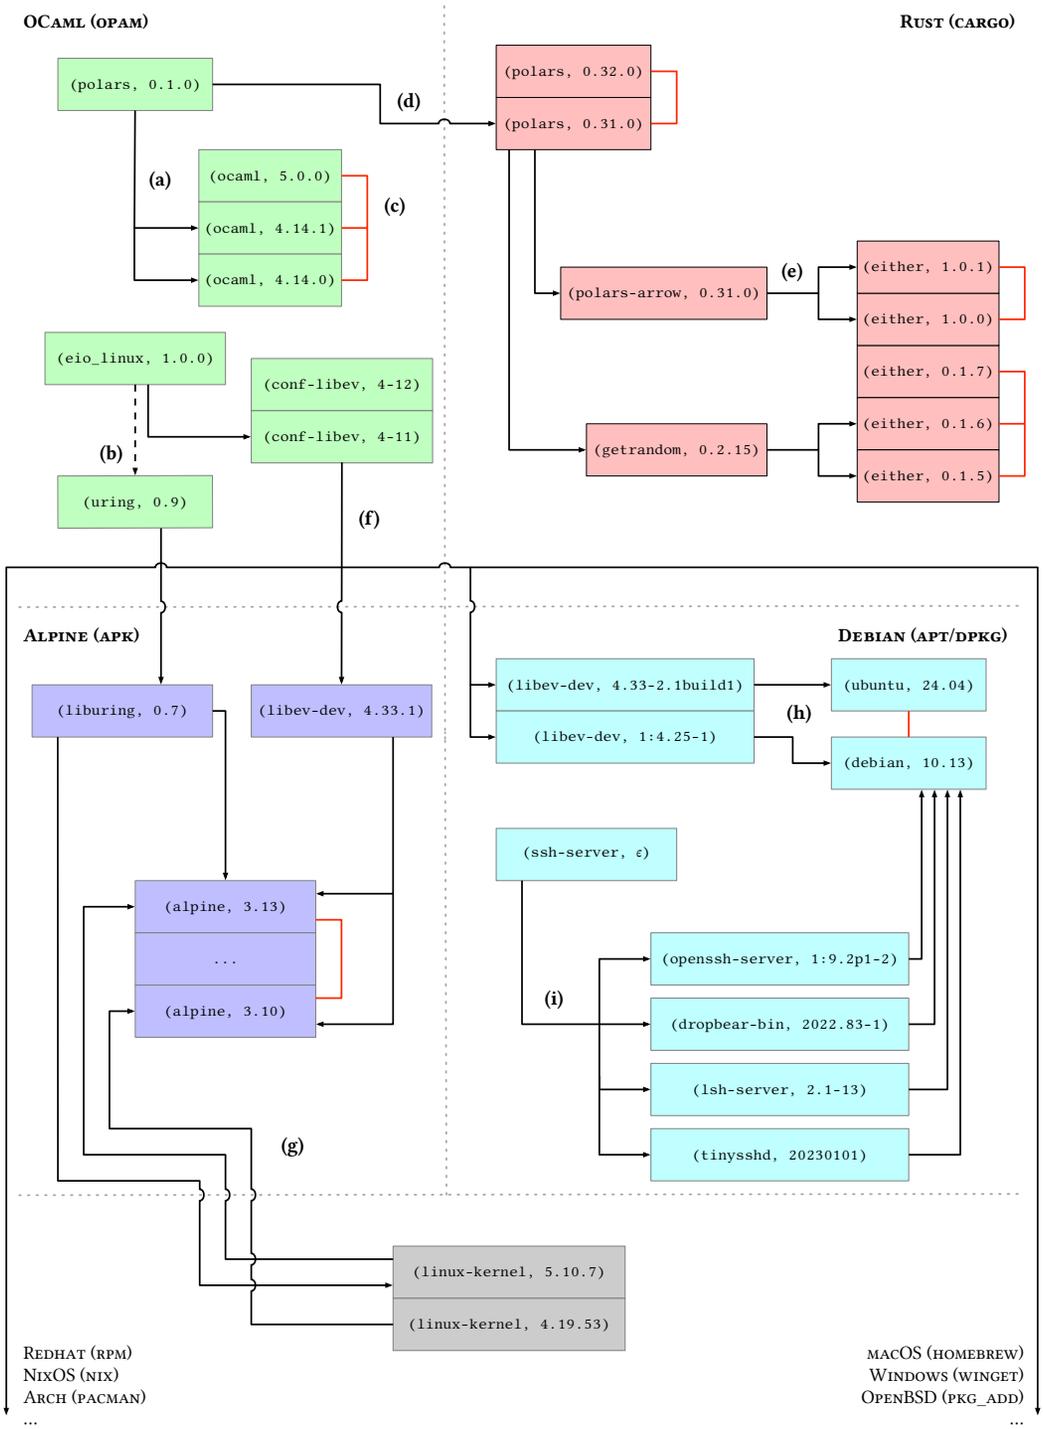

Fig. 1. An example cross-ecosystem hypergraph illustrating some of the challenges in package management.

1.1.1 Types of Dependencies. Figure 1 shows three types of relationships between packages:

Strong dependencies. A hypergraph is a graph where ‘hyperedges’ are between sets rather than individual vertices. One such hyperedge represents ‘dependency’ relationships where a package depends on a set of others, one of which can satisfy the dependency. This is represented by a solid black line. Note that we restrict the domain of directed hyperedges in our hypergraph to a size of 1 – dependencies can only be *from* one package. For example, Figure 1 (a) shows `polars` depending on the `ocaml` compiler with a hyperedge from $(\{\text{polars}, 0.1.0\}, \{\text{ocaml}, 4.14.1, \text{ocaml}, 4.14.0\})$. This means `polars` requires *either* `ocaml` with version 4.14.0 or 4.14.1. In a package manager file format¹ that is often expressed with a version formula such as `"ocaml" {>= "4.14.0" & < "5.0.0"}`. The fact that this relationship is a dependency is encoded in a labelling of the hyperedges.

Optional Dependencies. Another such hyperedge represents ‘optional dependency’ relationships, a set of packages which a package will use one of if present, but does not strongly require. Figure 1 (b) shows such a dependency from $(\text{eio_linux}, 1.0.0)$ to $(\text{uring}, 0.9)$, meaning that `eio_linux` can use the Linux IO libraries if they are installed, but otherwise falls back to more portable `libev`-based ones. Optional dependencies are commonly used to activate features across packages, such as enabling GPU support in a machine learning library if a GPU driver is present.

Conflicts. The final package relationship type is a ‘conflict’. In our running example, the OCaml toolchain only supports selecting a single version of a package, and so each `ocaml` package conflicts with every other `ocaml` package at Figure 1 (c), expressed as a (red) labelled hyperedge.

$$\begin{aligned} &(\{\text{ocaml}, 4.14.0\}, \{\text{ocaml}, 4.14.1, \text{ocaml}, 5.0.0\}) \\ &(\{\text{ocaml}, 4.14.1\}, \{\text{ocaml}, 4.14.0, \text{ocaml}, 5.0.0\}) \\ &(\{\text{ocaml}, 5.0.0\}, \{\text{ocaml}, 4.14.0, \text{ocaml}, 4.14.1\}) \end{aligned}$$

For the simplicity of diagramming we represent this as an undirected ‘conflict set’ where every package connected to the solid line conflicts with all the others. Rust, in contrast, supports multiple versions of the same library and so does not need these conflicts for its packages. Conflicts are usually introduced due to active software evolution such as incompatible APIs due to semantic versioning [17], or due to some negative trust relationship between packages such as a security vulnerability or a bug in a particular version of a package [50].

1.1.2 Cross-Ecosystem Dependency Resolution. The core dependency resolution problem [58] is based on the above three relationships. It consists of mapping this hypergraph to a graph with concrete versions selected for each dependency, with optional dependencies selected if they are present in the graph due to another dependency, and with no conflicting packages.

We have described dependencies within the OCaml ecosystem so far, but Figure 1 (d) introduces a dependency across ecosystem boundaries from OCaml to the Rust (`polars`, 0.31.0) package. Packages in different ecosystems are represented as vertices with a distinct namespace in the hypergraph, but that prefix is omitted in the diagram for clarity. This is a novel feature of HyperRes, as existing package managers do not support cross-ecosystem dependencies.

1.1.3 Multiple Versions of a Dependency. A transitive dependency of `(polars, 0.31.0)` is the `either` package, through `(polars-arrow, 0.31.0)` and `(getrandom, 0.2.15)`. However, they are dependent on different versions of the `either` package, leading to a diamond dependency problem (Figure 4) where two versions of the same package are required to satisfy the dependency chain (Figure 1 (e)). Some ecosystems forbid this behaviour (§2.2.5) due to toolchain limitations or policy (due to the complexity of reasoning about the resulting graph). Others, like the Rust

¹ In OCaml’s case, this is the `opam` [2] package manager; see Table 1 for details.

ecosystem, support using multiple versions of the same library if they have different major versions, so these dependencies of (`polars`, `0.31.0`) are satisfiable [5].

1.1.4 Operating System Dependencies. While cross-ecosystem dependency resolution is not supported by existing package managers, some such as `opam` have an ‘external dependency’ mechanism for installing system dependencies by invoking the system package manager [2]. External dependencies are platform dependent, for example,

```
["libev-dev"] {os-distribution = "debian"}
["libev-dev"] {os-distribution = "alpine"}
```

Figure 1 (f) shows this system dependency from `eio_linux` on `libev-dev` from either Debian or Alpine Linux, depending on which operating system the package is being installed on. For clarity, we omit the many possible, alternative systems that someone may be using. These system dependencies are unversioned in existing package managers, and a frequent source of user-facing problems if they update their system package manager without updating the corresponding packages in the language package manager. However, we can express these in HyperRes via cross-ecosystem dependencies (§1.1.2).

At the lower end of the userspace software stack, it is also common to have packages that are tied to a particular OS kernel version or other hardware availability. The `liburing` example in Figure 1 (g) shows how it depends not only on the Alpine OS version, but also the Linux kernel version. Another notable example of this class of problem is with handling the injection of GPU drivers into the software dependency stack, which is a common requirement for machine learning software running on the cloud [46].

1.1.5 Repository Selection. Debian Linux has package repositories associated with different releases of the operating system. The APT package manager uses the repository associated with the currently installed Debian version, each of which contain distinctly versioned binary packages. When upgrading the operating system, the package manager will select the repository associated with the new version and upgrade all packages to the new versions available in that repository.

HyperRes can identify which Debian release version satisfies a given package dependency query by modelling Debian and all of its releases as packages in the hypergraph. Figure 1 (h) shows (`libev-dev`, `1:4.33-2.1build1`) depending on Ubuntu 24.04 Noble (a variant of Debian) and (`libev-dev`, `1:4.25-1`) depending on Debian 10.13 (Buster).

1.1.6 Dependencies on Different Package Names. Except for our cross-ecosystem dependency in the Debian and Alpine namespaces (§1.1.4), we have so far only expressed dependencies on packages of the same name. However, several package managers (such as Debian) have a mechanism for expressing dependencies on virtual packages that can be satisfied by different implementation packages. Figure 1 (i) shows one such package — `ssh-server` — that is provided by either `openssh-server`, `dropbear-bin`, `lsh-server`, or `tinysshd`. These are represented naturally in the hypergraph a hyperedge to these various virtual packages.

Beyond this illustrative example, there are numerous other features of package managers that can be modelled in HyperRes, such as CPU architecture selection, operating system variants, feature flags for packages, optimisation flags, kernel version probing, and more. These parameters, along with the hypergraph structured described earlier, all form the set of inputs to a resolver that can output a single, consistent, and reproducible set of packages that can be deployed to a machine. We will next dive into how we can break down real-world package managers into a more digestible form for conversion to and from the HyperRes formalism.

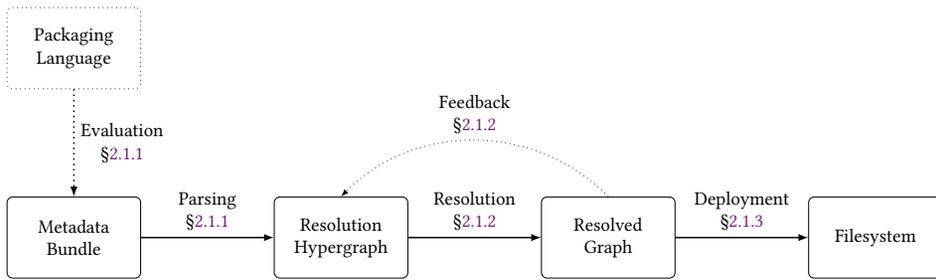

Fig. 2. The package management pipeline showing mappings between data structures, with dotted lines denoting optional components.

2 FINDING THE COMMON PIECES ACROSS PACKAGE MANAGERS

There are a lot of package managers in use in the wild, each with their own unique features and quirks, and the past two decades have seen a big surge in language-specific ones that sit alongside the more traditional system package managers. But across them all, there are commonalities that can be used to build a reusable semantic core, leaving a smaller set of differences to be modelled as special cases. We will now explore the design space of package managers by considering a representative selection of 36 out of a set of nearly 100 which we initially surveyed.² Before we dive into the details, we will first define a common vocabulary for the typical stages in a package management pipeline as mappings between the data structures in Figure 2.

2.1 The Package Management Pipeline

2.1.1 Parsing. Each package manager supports one or more repository formats, which are used to store the collection of available packages and consistency rules across them. The ‘metadata bundle’ is the collection of metadata associated with a given package that maps it into the package manager’s repository format. This is typically held outside the source code, since different package managers have different metadata formats and can update those independently of the releases of the downstream software. For example, Debian’s APT has a control archive in the `.deb` file format, OCaml’s opam has opam files, Rust’s Cargo has Cargo.toml files, and Nix [28, 29] has store derivation `.drv` JSON files.

This bundle may be contained in metadata files checked into version control for individual projects, and/or indexed in central repositories. For instance, APT has a control file in `.deb` files along with an archive of the binary package, but also has a Package archive containing the same data for every package in a repository. OCaml projects often have a `.opam` file checked into their version control repositories, and an opam repository contains the associated opam files for many projects, with a central ocaml/opam-repository representing the primary repository for that ecosystem.

Some package managers express their packages as embedded DSLs [35] in a host language (such as Homebrew with Ruby). An ‘evaluation’ step maps this packaging eDSL to the corresponding metadata bundle for that package (such as a JSON format in Homebrew). Other package managers have a tighter integration between their packaging language and the bundle format, and define a concrete DSL [19] exposed to users. Cabal and opam, for example, each have their own (different) DSLs to describe packages, supporting features like variable assignment and boolean algebra which also includes references to evaluation steps such as build scripts.

² The keen reader may wish to skip ahead to Table 1 to see the full set of package managers we model using HyperRes.

The set of metadata bundles per ecosystem are then parsed into our resolution hypergraph.

2.1.2 Resolution. The resolution hypergraph is a representation of the dependency resolution problem: given a set of version constraints, how do we find the freshest set of packages that satisfy them? The ‘resolution’ step maps the hypergraph to a simpler ‘resolved’ graph with concrete package versions selected. This problem is NP-hard, as noted in earlier work [12, 57, 58], but nowadays straightforward to solve using modern SAT solvers – if the right cost functions are applied to the resolution process.

Some package managers also take the existing installed state of the system into account when performing dependency resolution, denoted by the ‘feedback’ loop from the resolved graph to hypergraph. For example, Debian’s supports an ‘apt-get upgrade’ operation that modifies the version of a select set of packages to their latest versions, resolving any conflicts along the way.

Slackware is a notable exception to the norm in package management dependency resolution; official mechanisms do not provide any support for dependency tracking, instead relying on the user to manually install dependencies of a package. This reflects that distribution’s philosophy of simplicity and user control over a more rigorous dependency resolution system as found in (e.g.) Debian or Red Hat.

2.1.3 Deployment. The final mapping is from the resolved package graph to a filesystem subtree that can be deployed. In some specialised cases (such as embedded systems such as Busybox or Yocto), the deployment step may be to a firmware image rather than a filesystem, but the principle remains the same. The specifics of the deployment steps varies on the nature of the package manager. Source-based language package managers for dynamic languages such as JavaScript might simply place source code into a local directory, as npm does. System package managers that handle binary packages might unpack archives into the file system hierarchy. Other package managers might build the software according to instructions in the package metadata, as happens with cargo, opam or cabal.

Package managers might also make network requests to download source or binary code during deployment if a local repository is not present (e.g. opam), or have all the source code provided directly within the metadata bundle format (e.g. APT).

The specifics of how package managers manage resolved graphs varies, depending on how the clients handle state management. OCaml’s opam uses global or project-local ‘switches’, allowing multiple resolved graphs to live-side-by side [2]. JavaScript’s npm puts sources into a project-local `node_modules/` directory. APT uses dpkg to unpack prebuilt packages into the Linux Filesystem Hierarchy Standard (FHS). Nix places built packages at a path containing a cryptographic hash of their store derivation in the ‘Nix store’ (usually found in `/nix`). Meanwhile, Haiku OS deploys packages by mounting them in a union filesystem, allowing for layering and sharing of multiple packages.

2.2 A Categorisation of Package Managers

Table 1 fits the numerous package managers we surveyed into the pipeline in Figure 2. The table is a representative sample of interesting properties across the much larger set that we surveyed. For the purposes of brevity, we preferred open source ecosystems and did not include ‘app store’ managers like Google Play or Apple’s App Store, nor did we include package managers that are not primarily used for software deployment, such as TeX’s CTAN.

2.2.1 Ecosystems. The first section of Table 1 describes the particular use case a package manager was created for. As noted, package managers generally fall into two categories: language package managers and system package managers. The intended use for language package managers is in

Table 1. A comparison of representative package managers.

³ Package name and version pairs in the primary repository rounded to the nearest significant figure. ⁴ Whether a tool is a (P)ackage manager, (B)uild system, and/or a (C)ompiler. ⁵ pip previously used requirements.txt.

⁶ Cargo is a package manager and build system. ⁷ Installation sources (.msi,.msix,.appx,.exe) may manage their own dependencies. ⁸ Cabal is a package manager and build system. ⁹ Nix channels act as versioned repositories.

¹⁰ Debian often doesn't specify dependency versions and relies on a repository keeping a compatible package set. ¹¹ Installation sources (.msi,.msix,.appx,.exe) may manage their own dependencies. ¹² .tgz file format with JSON manifest. ¹³ Opam supports language-agnostic build scripts. ¹⁴ Limited support with 'Slotting'. ¹⁵ CRAN packages are installed from invoking an R function in the source of a package. ¹⁶ By manual name mangling, and only done for 1% of packages. ¹⁷ Slackware doesn't track dependencies. ¹⁸ Without subscription. ¹⁹ We only count the number of unique package names in PEAR as versioning information was not accessible.

²⁰ Go doesn't have a central repository. ²¹ Go doesn't use repositories by default, but can be configured to do so. ²² Go uses Minimal Version Selection [26]. ²³ The Go tool is a package manager, build system, and compiler.

²⁴ Bazel doesn't have a software repository, instead declaring 'external dependencies'. ²⁵ Bazel is a build system with package management functionality.

distributing libraries and tools to developers in a specific language, and system package managers in administrating a full operating system. The lines between these often blur; systems package managers do distribute language libraries, and language package managers can facilitate setting up a development environment with system dependencies. The system package managers tend to lag behind in the latest versions of libraries as they are more conservative in their updates, while language package managers typically offer less consistent integration across each other.

2.2.2 Repositories. Packages managers almost always group packages together in a centralised repository, allowing for discoverability and upgrades. Some package managers keep one main repository where changes are made continuously, dubbed a ‘rolling release’. Others periodically release a version of their repository, much as a new package version is released, representing a ‘versioned release’ of their operating system distribution. Security and other updates are usually backported to previous release of their repository for some time, creating ‘minor’ releases which should be safe for every user to upgrade to without risking software incompatibilities. Multiple repositories can be also often be combined with, for example, non-free packages, or unofficial user-contributed packages. A notable exception to this structure that does not require a package repository is Go, instead pointing to packages via a URL.

2.2.3 Bundling Mechanism. All package managers wrap an existing set of source code with some metadata to eventually install some entries into a filesystem, but the specifics can vary.

Source bundles. Some package managers only deal with deploying the sources for packages which are then built as part of a project, or interpreted. For example, the Go module system assembles all the sources before invoking its integrated build system. Others, such as npm, assemble the source packages (e.g. of JavaScript, an interpreted language) along with C bindings and other conventionally compiled files, and support builds via pre- or post-publishing scripts that can, for example, transpile from TypeScript to ES5 [10] or invoke a C compiler. Other approaches build projects using a shell script from the package metadata as part of deploying them (§2.1.3), like opam, Portage, and Nix. All of these are denoted as ‘source’ in Table 1.

Binary bundles. Some package managers — typically the operating system oriented ones — specifically have prebuilt binary packages as part of the bundle format. APT and RPM are two such examples; they begin their package lifecycle via source packages that are compiled to create multiple binary packages which are then installable by the end-user. These can be viewed as a staged version of source bundles, but with a concrete binary packaging format that is optimised for deployment for the resulting binaries that uses a simpler version specification than the source packages (§2.1.2). These are all denoted ‘binary’ in Table 1.

Evaluated bundles. Nix or Guix [25] are a combination of the above two schemes: they build projects in a sandboxed environment via a computed package specification DSL, with precisely specified inputs that track their dependency chains as the DSL is evaluated. This results in a single binary deployment of the collection of selected packages as a transparent optimisation of source deployment, but potentially requires much more recomputation by the end-user than a binary system. These are denoted as ‘evaluated’ in Table 1.

2.2.4 Dependency Formula. Version formulae are used by a package to express a set of possible packages that can satisfy a dependency. For example, a package depending on $1 \leq a \leq 3$ might depend on a set containing $a.1$, $a.2$, and $a.3$. Some package managers have limited dependency formulae consisting of a single range, others have arbitrarily complex boolean algebra, and others still support only specifying a *single* package that can satisfy a dependency. We differentiate between

those that support expressing a dependency on a set of possible packages versus those that can only depend on an exact package in the ‘dependency formula’ field of the table.

The ‘packaging language’ and ‘metadata bundle’ fields show the languages and formats described in Section 2.1.1. The ‘resolution hypergraph’ and ‘resolved graph’ fields show the tooling typically used to interact with these data structures. For example, apt is used for dependency resolution and, with a topological sort over the resolved graph, the lower-level dpkg is used to deploy individual binary packages. Finally, the ‘filesystem state’ field shows how the packages are deployed to the filesystem.

2.2.5 Concurrent Versions. Some package managers allow only one version of a package name in a resolved graph due to deployment constraints such as requiring unique symbols when linking objects, or storing packages at a unique path in the filesystem. For example, the OCaml toolchain does not support multiple versions of a package in the same switch. As such, while opam supports multiple resolved graphs living side-by-side in separate switches (§2.1.3), it doesn’t support multiple versions in one dependency resolution. System package managers often put a package at a particular path in the filesystem, so multiple versions of the same package would collide.

Other package managers allow multiple versions of the same package name existing in a resolved graph, ‘concurrent versions’, by supporting deploying multiple versions of the same package name. Cargo uses name mangling in order to support linking multiple versions of a single library into the same binary, where typically only one version can be used at the same time due to duplicate symbols. Note that Cargo only does this for packages with different major package versions as part of the semantic versioning scheme [5, 49]. Nix diverges from the Linux Filesystem Hierarchy Standard[3] to packages at paths containing unique cryptographic hashes, allowing the installation of multiple versions of a package on the same system.

2.2.6 Toolchain Integration. Some package managers, especially language package managers, have some degree of integration with other parts of the toolchain; build systems and compilers. Opam includes build scripts in package metadata which can invoke a build system or compiler, but is language-agnostic. This is similar to how a build system’s rules will include invocations to a compiler, such as a makefile target invoking gcc. Other ecosystems have tighter integration; cargo is the Rust ecosystem’s package manager and build system. The Go tool is a package manager, build system, and compiler. This enables functionality that might not be otherwise possible without a well-defined API between these parts of the toolchain. For example, Cargo’s concurrent version support is enabled by using knowledge of package management to provide unique symbols using package versions.

2.2.7 Sandboxing. Sandboxing is employed by package managers to ensure reproducibility and isolation during the build process. For example, opam and Nix sandbox builds when building packages for deployment (§2.2.3). The technologies used for sandboxing are often similar to those employed in containerisation and virtualisation. For example, Linux namespaces allow for the creation of lightweight environments where builds have access only to explicitly defined resources, such as specific file systems, process trees, and network interfaces. Sandboxing in package management is distinct from *reproducible builds*, which aim for bit-for-bit identical binaries and require determinism in all parts of the toolchain [38].

3 A FORMAL SYSTEM FOR DEPENDENCY RESOLUTION

In this section, we define the HyperRes formalism that allows us to reason about dependency resolution and extract a common core to package management. This addresses the resolution mapping (§2.1.2) from Figure 2.

3.1 HyperRes

The *resolution hypergraph* is a hyperedge-labelled directed hypergraph, where a hyperedge represents a relationship from one package to a set of packages. The type of this relationship is denoted by a hyperedge-label and is one of ‘dependency’, ‘optional dependency’, or ‘conflict’. The resolution hypergraph is resolved to a subgraph which satisfies the dependency constraints in a process we refer to as dependency resolution.

To start, we define a set of package names N , and a set of versions V_n for every package name n in N . The set of packages is often expressed with *dependency formula* (§2.2.4). Though there are many versioning schemes out there, we do not attach any particular semantics or ordering to versions. We define a set of all packages as name-version pairs,

$$P = \{(n, v) \mid n \in N, v \in V_n\}$$

A package $p \in P$ can express a dependency on a set of packages $d \subseteq P$, one of which can satisfy the dependency. Package p can have multiple dependencies, all of which must be satisfied. Similarly, a package p can express an optional dependency on a set of packages $o \subseteq P$, one of which can satisfy the dependency; and a conflict on a set of packages $c \subseteq P$ which p cannot co-exist with. We define functions $deps : P \rightarrow 2^{2^P}$ mapping a package to the set of its dependencies, $opts : P \rightarrow 2^{2^P}$ mapping a package to set of its optional dependencies, and $conflicts : P \rightarrow 2^{2^P}$ mapping a package to the set of its conflicts. We define a set of ordered pairs of relationships as,

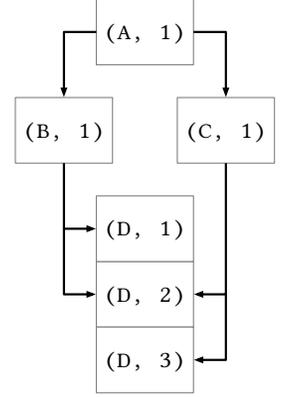

$$\begin{aligned} R = & \{(\{p\}, d) \in 2^P \times 2^P \mid p \in P, d \in deps(p)\} \\ & \cup \{(\{p\}, o) \in 2^P \times 2^P \mid p \in P, o \in opts(p)\} \\ & \cup \{(\{p\}, c) \in 2^P \times 2^P \mid p \in P, c \in conflicts(p)\} \end{aligned}$$

We define the resolution hypergraph as a directed hypergraph H with vertices P and hyperedges R , where hyperedges from a package (the domain) to a set of packages (the codomain) [20]. Note that we restrict the domain to a size of one – we can only express a dependency *from* one package.

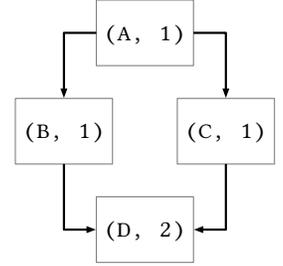

We define labels for the hyperedges of our hypergraph as a mapping $L : 2^P \times 2^P \rightarrow T$ from hyperedges to a relationship $T = \{\delta, \sigma, \gamma\}$, where δ encodes a dependency, σ an optional dependency, and γ a conflict. Note that this means we cannot depend, optionally depend, or conflict with the same package set.

$$\begin{aligned} \forall p \in P, \forall d \in deps(p), L(\{p\}, d) &= \delta \\ \forall o \in opts(p), L(\{p\}, o) &= \sigma \\ \forall c \in conflicts(p), L(\{p\}, c) &= \gamma \end{aligned}$$

We define the dependency resolution problem as mapping a set of query packages Q and the resolution hypergraph H , to resolved graph G , selecting packages to satisfy dependency constraints. Formally, given a set of packages $Q \subseteq P$ and a hyperedge-labelled directed hypergraph H , *resolution* builds a directed graph G with vertices $V(G)$ and edges $E(G)$ where,

(a) A resolution hypergraph H .

(b) A resolved graph G .

Fig. 3. Example of a resolution from H and $q = A1$ to G .

- (1) G contains the query packages,

$$\forall q \in Q, q \in V(G)$$

- (2) G satisfies dependencies,

$$\forall p \in V(G), \forall d \in \text{deps}(p), \exists! e \in d : (p, e) \in E(G) \wedge e \in V(G)$$

If a package p is in $V(G)$ and d is a dependency of p ; then exactly one package e , that satisfies d , is in an edge from p to e ; and e is also in $V(G)$.

- (3) G satisfies optional dependencies,

$$\forall p \in V(G), \forall o \in \text{opts}(p), (\exists e \in o : e \in V(G)) \implies (\exists! e \in o, (p, e) \in E(G))$$

If package p has its optional dependency o satisfied by a package in $V(G)$, then there is exactly one package e that satisfies that dependency in an edge from p to e .

- (4) G satisfies conflicts,

$$\forall p \in V(G), \forall c \in \text{conflicts}(p), p \in V(G) \implies (c \cap V(G) = \emptyset)$$

If package p is in $V(G)$ then no package p conflicts with is in $V(G)$.

An illustrated hypergraph is shown in figure 3, which is resolved to graph G according to these dependency constraints. Formally, hypergraph H has $\forall r \in R, L(r) = \delta$ and,

$$R = \{(\{A1\}, \{B1\}), (\{A1\}, \{C1\}), (\{B1\}, \{D1, D2\}), (\{C1\}, \{D2, D3\})\}$$

This hypergraph is resolved, with $Q = \{A1\}$ to a graph G with

$$E(G) = \{(A1, B1), (A1, C1), (B1, D2), (C1, D2)\}$$

3.2 NP-completeness

We define the `DEPENDENCYRESOLUTION` decision problem as whether a G exists for a given Q and H . We can show the `DEPENDENCYRESOLUTION` decision problem is NP-complete by proving that it is in NP and that it is NP-hard. First, `DEPENDENCYRESOLUTION` is in NP as it has a proof, G , which can be verified in polynomial time by checking that G , (1) contains the query packages, (2) satisfies dependencies, (3) satisfies optional dependencies, (4) satisfies conflicts. This requires iterating over every vertex and edge in G , so can be done in polynomial time.

Second, we can prove that `DEPENDENCYRESOLUTION` is NP-hard by a polynomial time reduction from the *boolean satisfiability problem* (SAT), which is well-known to be NP-complete [24]. The SAT instance is defined as a formula F in conjunctive normal form (CNF) with x variables and y clauses. To construct an instance of `DEPENDENCYRESOLUTION` from an instance of SAT,

- (1) For each variable we define two packages representing true and false value assignments, $(n_i, \text{TRUE}), (n_i, \text{FALSE}) \in P \mid 1 \leq i \leq x$ where $n_i \in N$ and $\{\text{FALSE}, \text{TRUE}\} = V_{n_i}$.

The two packages representing true and value assignments for the same variable conflict,

$$\text{conflicts}((n_i, \text{TRUE})) = \{(n_i, \text{FALSE})\}, \text{conflicts}((n_i, \text{FALSE})) = \{(n_i, \text{TRUE})\} \mid 1 \leq i \leq x$$

- (2) For each clause we create a package with a dependency that is the set of packages corresponding to literals in the clause, with versions satisfying the literal polarity. We create a package for each clause $(c_j, \epsilon) \in P \mid 1 \leq j \leq y$ where $c_j \in N$ and $\{\epsilon\} = V_{c_j}$. Let the k^{th} literal in this clause have variable $n_{j,k}$ and let l_j denote the number of literals in clause c_j . Let $b_{j,k}$ represent the polarity of the literal k^{th} literal, where $b_{j,k} = \text{TRUE}$ if the literal is positive and $b_{j,k} = \text{FALSE}$ if the literal is negative. We define,

$$\text{deps}(c_j) = \{(v_{j,k}, b_{j,k}) \mid 0 \leq k \leq l_j\} \mid 1 \leq j \leq y$$

- (3) We define $Q = \{q\}$ as the query package set, with $deps(q) = \{\{c_j\} \mid 1 \leq j \leq y\}$, which represents the formula F .

Note that we express disjunctions in clauses with multiple packages that can satisfy a single dependency, and conjunctions between clauses with multiple dependencies.

The reduction process can be performed in polynomial time. Creating packages and package conflicts for x variables takes $O(x)$ time. Creating packages for y clauses takes $O(y)$ time. And creating dependencies for each clause takes time proportional to the numbers of literals in the clause. Letting l denote the total number of literals across all clauses, then creating dependencies for all clauses takes $O(l)$ time. The total time complexity for the reduction is $O(x + y + l)$, which is classified as polynomial time.

Finding a package set that satisfies all dependencies is equivalent to finding a truth assignment that satisfies all clauses, therefore the reduction holds and `DEPENDENCYRESOLUTION` is NP-hard. Since `DEPENDENCYRESOLUTION` is both in NP and NP-hard, it is NP-complete.

3.3 Resolution with SAT Solvers

We express a SAT instance as an `DEPENDENCYRESOLUTION` instance to prove that it is NP-hard, but we can also express a `DEPENDENCYRESOLUTION` instance as a SAT instance to perform dependency resolution with a SAT solver. First, for each package we create a Boolean variable $\forall p \in P, \exists X_p$; and for each package that satisfies a dependency we create a boolean variable $\forall (p, d) \in D, \forall e \in d, \exists X_{(p,e)}$. We then create a SAT instance in conjunctive normal form containing:

- (1) Clauses to select the query packages $\forall q \in Q, (X_q)$.
- (2) A clause that states if a package is chosen to satisfy a dependency then that package must be selected,

$$\forall p \in P, \forall d \in deps(p), \forall e \in d, (\neg X_{(p,e)} \vee X_e)$$

For each dependency of each package, a clause that states if the package is selected at least one package must satisfy that dependency,

$$\forall p \in P, \forall d \in deps(p), d = \{e_1, e_2, \dots, e_{|d|}\}, \left(\neg X_p \vee X_{(p,e_1)} \vee X_{(p,e_2)} \vee X_{(p,e_3)} \vee \dots \vee X_{(p,e_{|d|})} \right)$$

And a set of clauses to ensure that at most one element is chosen to satisfy the dependency,

$$\forall p \in P, \forall d \in deps(p), \forall e_1, e_2 \in d \text{ where } e_1 \neq e_2, (\neg X_{(p,e_1)} \vee \neg X_{(p,e_2)})$$

- (3) For each optional dependency of each package, a set of clauses that state if a package that satisfies the optional dependency is selected, at least one package must satisfy the optional dependency,

$$\forall p \in P, \forall o \in opts, \forall e \in o, o = \{e_1, e_2, \dots, e_{|o|}\}, \left(\neg X_p \vee \neg X_e \vee X_{(p,e_1)} \vee X_{(p,e_2)} \vee X_{(p,e_3)} \vee \dots \vee X_{(p,e_{|o|})} \right)$$

A set of clauses that state if a package satisfies an optional dependency then it must be selected,

$$\forall p \in P, \forall o \in opts, \forall e \in o, (\neg X_{(p,e)} \vee X_e)$$

And a set of clauses to ensure that at most one element is chosen to satisfy the optional dependency,

$$\forall p \in P, \forall o \in opts(p), \forall e_1, e_2 \in d \text{ where } e_1 \neq e_2, (\neg X_{(p,e_1)} \vee \neg X_{(p,e_2)})$$

- (4) A set of clauses that ensure conflicting packages are not present,

$$\forall p \in P, \forall c \in conflicts(p), \forall e \in c, (\neg X_p \vee \neg X_e)$$

We can extract G from the SAT solution, where $X_p \Leftrightarrow p \in V(G)$, and $X_{p,d} \Leftrightarrow (p, e) \in E(G)$. By our construction of the SAT instance this means G satisfies the `DEPENDENCYRESOLUTION` constraints (§3.1). Hence, if there is a satisfying assignment for the SAT instance, there is a valid resolution in the `DEPENDENCYRESOLUTION` instance, and this reduction is sound.

Given a solution for the `DEPENDENCYRESOLUTION` instance we can extract an assignment of variables, where $p \in V(G) \Leftrightarrow X_p$, and $(p, e) \in E(G) \Leftrightarrow X_{p,d}$. This assignment satisfies all the clauses in the CNF of the SAT instance by the construction method. Hence, if there is a solution to the `DEPENDENCYRESOLUTION` instance, then there is a satisfying assignment in the SAT instance, and this reduction is complete.

We emphasise that this is not designed to be an efficient SAT encoding, rather to demonstrate that this formalism can be mechanically solved.

4 MODELLING PACKAGE MANAGERS

In this section we will illustrate how a variety of properties of real-world package managers (§2) can be modelled in the HyperRes formalism (§3). This formalism has been defined to be as minimal as possible to capture the common core of package management, but is expressive enough to model complex functionality such as boolean algebra (§4.2.1) and features parameterisation (§4.3.2).

4.1 APT

APT is the package manager for the Debian Linux distribution (Table 1). It manages system-wide packages, ensuring that dependencies are met and conflicts are avoided. It handles a single version of a package at a time, and supports virtual packages which allow multiple packages to provide the same functionality.

4.1.1 Single Versions. As with many packages managers APT only supports deploying a single version of a package name at a time (§2.2.5). We can encode this in the HyperRes formalism by saying for each package p , $\text{conflicts}(p)$ contains every other package with the same package name,

$$\forall (n, v) \in P, \{(n, v') \mid v' \in V_n, v' \neq v\} \subseteq \text{conflicts}((n, v))$$

This means that for all package names in $V(G)$, there exists exactly one version for each,

$$\forall (n, v) \in V(G), \forall (n', v') \in V(G), n = n' \implies v = v'$$

Consider a hypergraph as depicted in Figure 4, where only a single version of a package name is allowed, as encoded as a conflict between D1 and D2. Note that for diagramming simplicity we represent this as an undirected ‘conflict set’ where every package connected to the solid line conflicts with all the others. This hypergraph exhibits the ‘diamond dependency problem’, so called as the graph with edges $\{(A, B), (A, C), (B, D), (C, D)\}$ forms a diamond, which has no solution. Formally, H has,

$$\begin{aligned} D &= \{(\{A1\}, \{B1\}), (\{A1\}, \{C1\}), (\{B1\}, \{D1\}), (\{C1\}, \{D3\})\} \\ C &= \{(\{D1\}, \{D3\}), (\{D3\}, \{D1\})\} \\ \forall r \in D, L(r) &= \delta \quad \forall r \in C, L(r) = \gamma \quad R = D \cup C \end{aligned}$$

4.1.2 Version Ordering. Like many package managers APT imposes a total lexicographical ordering of versions [6]. For example, version 2.0 of a package will be greater than version 1.0. The

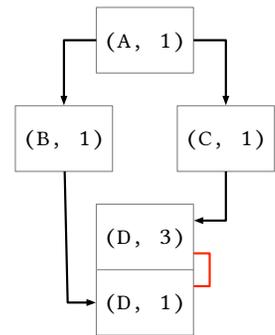

Fig. 4. A resolution hypergraph H exhibiting the ‘diamond problem’.

dependency resolution problem does not specify a preference, but an algorithm to solve the problem can take this into account by trying packages with higher versions first. For example, if we create literals in a SAT clause (§3.3) according to this ordering and try literals in the order they appear in the clause, we will prefer higher versions.

4.1.3 Upgrades. The feedback mapping in Figure 2 shows an input from the resolved graph into the resolution graph, but the HyperRes formalism doesn't take the existing state of the system into account. HyperRes doesn't consider how package managers like APT are used to upgrade individual packages. We can model this by pinning installed versions in our query set.

Consider a scenario where we have updated the Debian repository (§2.2.2) and want to upgrade a single package to a new version. We can represent this in our formalism by creating a virtual package that has a dependency set containing the versions greater than the current versions of the package name being upgraded, as well as a dependency on every other installed package. To deploy the upgrade we can take the difference from the resulting resolved graph and the pre-upgrade resolved graph, removing and adding packages as appropriate. This doesn't consider a scenario where the upgraded package and existing packages can't co-exist.

If there's a conflict with the versions of the installed packages, we can depend on their greater versions. That is, for each installed package name, add a dependency set on the current version and any greater versions to the virtual package. Figure 5 shows a resolution hypergraph with a virtual package q where $Q = \{q\}$ expressing an upgrade on package $A1$ with an installed package $B1$. The installed package $B1$ conflicts with the new version of A , so $B1$ will also need upgrading. We could express a preference for minimising upgrades with an ordering of these installed package versions preferring lower versions (§4.1.2).

The Common Upgradeability Description Format (CUDF) [56] provides a standard format for expressing such upgrade problems that can be solved by various algorithms.

4.1.4 Virtual Packages. APT packages can express dependencies on virtual packages that other packages 'provide' [7]. For example, both `openssh-server` and `dropbear-bin` provide the virtual package `openssh-server`. We can encode a dependency on a virtual package in the resolution hypergraph with a dependency on the set of all packages which provide it, as depicted in Figure 1 (§1.1.6). Assuming a set of virtual packages P_v and a function which contains the set of virtual packages a provided by a package, $provides : P \rightarrow 2^P$, we can formally define this encoding with,

$$\forall p_v \in P_v, deps(p_v) = \{\{p \mid p_v \in provides(p), \forall p \in P\}\}$$

4.1.5 Computer Architecture. Packages managers that provide binary packages often provide different versions of a package for different architectures, and APT is no exception. APT points to different package versions depending on the architecture of the machine it is running on. We can encode computer architecture as a package in the resolution hypergraph in order to support resolving for a particular architecture.

We create a name `arch` in N . The versions of this name will be the enumeration of supported architectures, e.g.

$$\{x86_64, ARM64, i386\} = V_{arch}$$

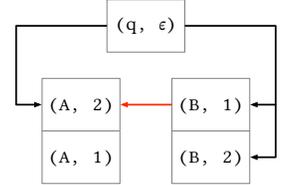

Fig. 5. A resolution hypergraph expressing an upgrade.

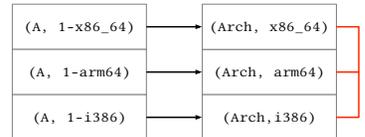

Fig. 6. Encoding computer architecture in the resolution hypergraph.

We define conflicts between all the architecture versions to force a selection,

$$\forall v \in V_{\text{arch}}, \{(\text{arch}, v') \mid v' \in V_{\text{arch}}, v' \neq v\} \subseteq \text{conflicts}((\text{arch}, v))$$

The associated architecture for a debian package can be added as a dependency. Figure 6 shows a package A with versions 1-x86_64, 1-ARM64, and 1-i386 depending on the appropriate arch version. By including an arch package in the query set a resolve can be restricted according to the hardware available.

4.2 Opam

Opam is the package manager for the OCaml programming language (Table 1). It supports complex dependency formulae with global and local variables, and requires an acyclic resolved dependency graph to perform build steps in an order such that all the dependencies of a package are built before it is built.

4.2.1 Dependency Formula.

Boolean Algebra. Opam supports ‘package formula’ and ‘version formula’, boolean algebra of packages names and package versions respectively [2]. As we have shown (§3.2) we can encode a SAT expression in our HyperRes formalism, and can encode opam’s package formulae in the same way. Disjunctions can be represented by a dependency set, conjunctions with a ‘virtual’ package that depends on both the operands of the conjunctions, and negations with conflicts.

Figure 7 demonstrates how boolean algebra can be represented in HyperRes with a dependency from A1 that corresponds to the boolean expression, $(B1 \wedge C1) \vee (\neg C1 \wedge B2)$. Note that the & symbol represents a virtual package with an empty version ϵ and a globally unique name.

Variables. Opam also supports global and package-local variables in its package formulae. With the global `os-distribution` variable in a package formula, the formula’s dependency will be conditional on the operating system the package manager is deploying the package on (§1.1.4). We can encode this in resolution hypergraph as we did with computer architecture for APT (§4.1.5). That is, we create a package `os-distribution` with versions enumerating the possible operating system distributions. For a package dependent upon `["gcc"] {"os-distribution" = "debian"}` we can depend on a virtual package which itself depends on the `os-distribution` package with version `debian`, and a version of `gcc`.

Package-local variables can be encoded as optional dependencies. The package-local `with-test` denotes variables that are only required if tests have been enabled for the package. For example, consider a package `(polars, 0.1.0)` that has a dependency on `"alcotest" {"with-test"}`. We can create a virtual package `(polars, (0.1.0, test))` which `(polars, 0.1.0)` optionally depends on, where `(polars, (0.1.0, test))` depends on `alcotest`. To enable tests for `(polars, 0.1.0)` the package `(polars, (0.1.0, test))` can be installed.

4.2.2 Acyclic Resolved Graph. Opam has an additional requirement for the resolved graph over those specified in section 3.1, that it must be *acyclic*. As part of its deployment (§2.1.3) opam performs a topological sort of the graph – which is only possible with a directed acyclic graph – to assemble a list of actions to be executed sequentially. These actions build packages, and if all the required dependencies of a package aren’t provided prior to its build, the build will fail. An exception to this is packages marked with the `post` variable, which denotes where the cycle can be broken as a dependency isn’t a build-time dependency. Other package managers deal with cycles

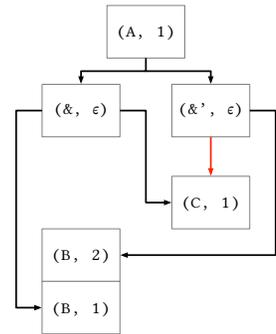

Fig. 7. Encoding boolean algebra in a hypergraph.

by breaking them at some arbitrary point, like APT with binary packages [7]; or not performing a topological sort at all, npm lays out files and relies on language support to break cycles between modules.

We can formally define this as for the resolved graph G , for any sequence of edges e_1, e_2, \dots, e_n in G where $e_i = (p_i, e_i)$, for $1 \leq i \leq n$, it holds that $p_i \neq p_{i+1}$ for any $1 \leq i < n$.

4.3 Cargo

Cargo is the package manager is the Rust language's package manager and build system (Table 1). It supports multiple versions of the same package coexisting in a project, provided they have different major versions. It also uses features to enable or disable optional functionality in packages.

4.3.1 Concurrent Versions. As discussed in section 2.2.5, Cargo supports multiple versions of packages in a resolved graph. To be precise, it only allows different major version numbers in the semantic versioning scheme [5, 49]. To model this in the HyperRes formalism, we can add conflicts as described in section 4.1.1, but only if the packages share the same major version. Figure 1 demonstrates this (§1.1.3).

This easing of the constraints allows a solution to the diamond dependency problem from Figure 4. If we remove the conflicts set C , and let $R = D$, then G in Figure 8 represents a solution.

4.3.2 Features. Rust supports parametrising packages with features. For example, the regex package has features to enable performance optimisations and Unicode support. When enabled features can require additional dependencies. Packages express features that they require when depending on a package, and when resolving dependencies packages will take the union of all the features that they are depended upon with. We will describe an extension to the HyperRes formalism to support parametrising dependencies with features, and show how we can encode this extended formalism using versions in the original formal system.

Extending HyperRes to support features. To start, we define a set of package features for every package, $\forall p \in P, \exists F_p \subseteq F$ and F as the set of all possible features. Then, we define a multi-label function mapping the dependency hyperedges of the resolution hypergraph H to sets of features required for the dependency. We define this mapping $L_F : 2^P \times 2^P \rightarrow F$ where $\forall p \in P, \forall d \in \text{deps}(p), L_F(\{\{p\}, d\})$ is the set of features required by hyperedge $(\{p\}, d)$. Note that we assume the same feature set can be applied to all packages that can satisfy a dependency, $\forall p \in P, \forall d \in \text{deps}(p), \exists F_d : e \in d \implies F_e = F_d$.

We add a criterion to the dependency resolution problem, that G unifies features, with a multi-label function mapping the vertices of the resolved graph G to sets of features used by that package $L_V : P \rightarrow F$.

$$\forall p \in V(G), \forall d \in \text{deps}(p), \exists! e \in d : (p, e) \in E(G), L_F(\{\{p\}, d\}) \subseteq L_V(e)$$

Meaning that for each package e chosen to satisfy dependency d of package p , the features selected for $e - L_V(e)$ - must include the features required by dependency $d - L_F(\{p\}, d)$.

The features of a package can affect its dependencies, we define a function $f_{\text{deps}} : P \times F \rightarrow 2^{2^P}$ function which maps a package and its feature to a set of additional dependencies required by that

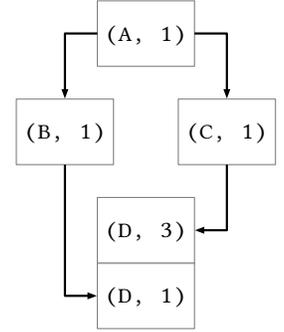

Fig. 8. A multi-version resolved graph G .

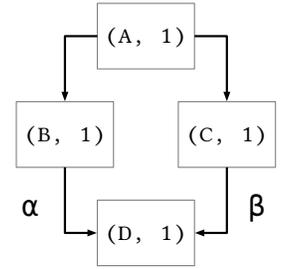

Fig. 9. A resolution hypergraph where hyperedges are parameterised by features.

feature. We add another criterion of HyperRes that G satisfies feature dependencies,

$$\forall p \in V(G), \forall f \in L_V(p), \forall d \in fdeps((p, f)), \\ \exists! e \in d : (p, e) \in E(G) \wedge e \in V(G)$$

Meaning if a package p is in $V(G)$ with features f selected, and d is a dependency of p with features f ; then exactly one package e , that satisfies d , is in an edge from p to e ; and e is also in $V(G)$.

Figure 9 shows an example hypergraph where $B1$ depends on $D1$ with feature α and $C1$ depends on $D1$ with feature β . Formally,

$$F_{D1} = \{\alpha, \beta\}, \quad L_F(\{\{B1\}, \{D1\}\}) = \alpha, \quad L_F(\{\{C1\}, \{D1\}\}) = \beta$$

Encoding the extended formalism in HyperRes. To show that the HyperRes formalism is expressive enough to describe features, we will encode the extended formalism in the HyperRes formalism. For every package name we define a ‘feature version’ set as pairs of version and feature supported by that version,

$$\forall n \in N, \exists FV_n = \{(v, s) \mid f \in F_{(n,v)}, v \in V_n\}$$

Assuming an ordering of features, and a new separator, we can encode this feature version as a string. If we had a package name D with version 1, and features a and b , we could encode the new versions as $1+a$ and $1+b$.

We define a new version set for each package name containing the normal versions and feature versions,

$$\forall n \in N, \exists V'_n = V_n \cup FV_n$$

And we define a new package set,

$$P' = \{(n, v) \mid n \in N, v \in V'_n\}$$

We define a new dependency function $deps'$ and let,

$$\forall n \in N, \forall (v, f) \in FV_n, deps'((n, (v, f))) = \{(n, v)\} \cup fdeps((n, v), f)$$

Meaning for every new feature version package we depend on the corresponding package version without the feature version; as well as any new dependencies introduced by said feature. So package $(D, 1+a)$ would depend on package $(D, 1)$. We also let,

$$\forall p \in P, deps'(p) = deps(p) \cup \{(n, (v, f)) \mid (n, v) \in d \mid \forall f \in L_F(\{\{p\}, d\}), d \in deps(p)\}$$

Meaning where we depended on a package p , we now also depend on the versions representing the features that we depended on p with. If we depended on a package with D with version 1 and feature a , we would now depend on versions 1 and $1+a$.

We construct the hypergraph as before with P' in place of P and $deps'$ in place of $deps$. Figure 10 shows an example of an encoding of Figure 9 with this scheme. Note that we omit separators between versions and features for the sake of brevity.

With a resolution to a resolved graph G' , we can extract the feature set of packages in P with,

$$\forall n \in N, \forall (v, f) \in VF_n, (n, (v, f)) \in V(G') \implies f \in L_V((n, v))$$

And the dependencies introduced by feature selection with,

$$\forall n \in N, \forall (v, f) \in VF_n, \{(n, (v, f)), d\} \in E(G') \implies (\{(n, v)\}, d) \in E(G)$$

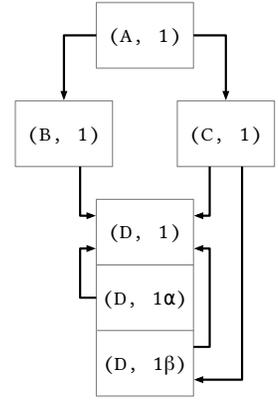

Fig. 10. A resolution hypergraph where features are encoded as optional dependencies.

4.4 Nix

Nix is a package manager that pioneered the functional model of software deployment [28]. It describes packages in Nix DSL expressions which are ‘translated’ with `nix-instantiate` to store derivations, a JSON file describing the inputs, outputs, and build steps of a derivation (package). Store derivations are ‘realised’ into files in the Nix store with `nix-store -realise`. In our package management pipeline the translation is modelled as evaluation of the packaging language to bundle format, and realisation as deployment of the bundle formats to the filesystem (Table 1).

4.4.1 Specific dependencies. The store derivation format of Nix does not support expressing a set of possible packages that can satisfy a dependency, instead pointing to the exact package required. We can model this in the resolution hypergraph by restricting the codomain to a size of one,

$$\forall r \in R, r = (\{p\}, \{e\}) : p \in P \wedge e \in P$$

Nix also does not support optional dependencies or conflicts $\forall r \in R, L(r) = \delta$. Instead of optional dependencies, derivations are generated by functions in the Nix DSL which can be parameterised to enable varying functionality. And as Nix stores components at paths containing unique cryptographic hashes, it allows multiple packages to co-exist that would otherwise conflict with each other (§2.2.5). This turns the dependency resolution problem to a simple walk of the tree where satisfying dependencies means,

$$\forall p \in V(G) : \text{deps}(p) = \{e\}, (p, e) \in E(G) \wedge e \in V(G)$$

5 BRIDGING ECOSYSTEMS

Having established that HyperRes (§3) can model a wide array of package managers individually (§4), we now turn our attention to the bigger picture of how to unify these ecosystems by resolving dependencies across them all. We aim to enable projects that span multiple languages and platforms to manage their dependencies coherently, overcoming the current fragmentation caused by incompatible package management systems.

We thus extend the HyperRes formalism to support cross-ecosystem dependencies (§5.1), demonstrate how to resolve such dependencies (§5.2), and outline how translating packages bidirectionally between ecosystems is now possible (§5.3).

5.1 HyperRes for Multiple Ecosystems

Our early example in Figure 1 shows a resolution hypergraph including packages from multiple different ecosystems, with some dependencies transcending these boundaries. To introduce this notion of ecosystem to the HyperRes formalism, we can add an ecosystem vertex labelling to distinguish packages belonging to different ecosystems.

We define a set of ecosystems T , with a package namespace for each $\forall t \in T, \exists N_t$. We define the set of names $N = \{n \mid n \in N_t, t \in T\}$, and a package set for each ecosystem using the version sets as previously defined $\forall t \in T, P_t = \{(n, v) \mid v \in V_n, n \in N\}$. And we define an ecosystem labelling function, $L_e : P \rightarrow T$ as, $\forall t \in T, \forall p \in P_t, L_e(p) = t$. Cross-ecosystem relationships are relationships where, $(\{p\}, \{d\}) \in R, \exists e \in d : L_e(p) \neq L_e$.

We distinguish between ecosystems with this labelling as they differ in how their metadata bundles are parsed to create a hypergraph (the ‘on-ramp’ to the formalism from the ecosystem), and how packages in the resolved graph are provided (the ‘off-ramp’ to the formalism to invoke the lower-level installer for that ecosystem).

This allows HyperRes graphs to be resolved in one pass *across* ecosystems with *no modification* to HyperRes aside from this additional labelling. In this cross-ecosystem HyperRes, we can include multiple repositories in any ecosystem modelled by packages. This lets us, for example, determine

which version of Debian Linux would provide the required version of a language dependency (§1.1.5). We can also include the default Linux kernel version provided by various repository versions as a cross-ecosystem package (1.1.4), allowing for low-level dependencies or GPU drivers to be resolved reliably, and percolate these constraints higher up the stack into language-specific ecosystems such as Python’s. We can further model constraints such as computer architecture (§4.1.5) to select for optimised or hardware-dependent solutions, or do the opposite and scan for a portability matrix for a given software release.

5.2 Cross-Ecosystem Resolution

We have implemented a number of translations from ecosystem-specific metadata bundles to a prototype HyperRes encoding. For some package managers, like APT and APK, this involves parsing and translating static metadata. For others with tighter integration between their packaging language and metadata bundles, like opam and Cabal (§2.1.1), OCaml and Haskell libraries were used to interpret opam and Cabal files to an in-memory representation that was translated to the HyperRes encoding. We currently have translations from APK, Cabal, Cargo, CentOS, Debian, Fedora, Homebrew, opam, OpenSUSE, and Pacman; totalling just over 1.7 million packages.

While none of these ecosystems natively supports cross-ecosystem resolving, we can add these ecosystem-transcending dependencies (§1.1.2). Packages which vendor packages from other ecosystems are a prime example, like the polars OCaml package with a number of Rust packages. Another is packages which have some ad-hoc mechanism for invoking system packages managers to provide dependencies, such as opam’s external dependencies mechanism. We can mechanically translate external dependencies to cross-ecosystem dependencies for various operating systems.

We have written a custom resolver to operate on this hypergraph using a SAT encoding. Despite the large number of packages, the performance of the resolution is a function of the size of the dependency cone and has remained tractable thus far. Figure 11 diagrams a subgraph of the resolved graph resulting from the query set containing opam’s polars.1.0.0 library described in Figure 1. The Debian dependencies come from a dependency on the system Rust compiler (Figure 11 (a)), and the Cargo packages come from the Rust component of this bindings library. Note the cycle between deb-libgcc1.1-8.3.0-6 and deb-libc6.2.28-10+deb10u1 which is broken by Debian [7] (Figure 11 (b)), and the cycle between opam-ocaml.4.14.3 and opam-ocaml-variants.4.14.3+trunk which is broken by a post variable (Figure 11 (c)) [2]. Also note the use of optional dependencies which have been resolved to a concrete set of features encoded as dependencies of opam-ocaml-variants.4.14.3+trunk. In the current state these Rust dependencies are vendored into the projects source repository, and Debian dependencies are ad-hoc and unversioned.

As every ecosystem has a different translation to the resolution hypergraph, so they all have a different mechanism of providing the resulting packages (§2.1.3). Some are easier to integrate than others. We can perform a topological sort over the resolved graph and, for example, Debian’s dpkg can be easily invoked to install a single package. Alpine’s APK can be used to install a package and resolve dependencies, but if we invoke it in topological order it will simply verify that our resolve has indeed provided all the required dependencies. Even monolithic tools like Rust’s Cargo can similarly be invoked to provide HyperRes resolved dependencies.

5.3 Ecosystem Translations

So far, we discussed the $N + N$ problem for N ecosystems: we write translations from ecosystem metadata to the resolution hypergraph (N) and interface with ecosystem tooling in order to deploy them (N). This allows us to resolve dependencies across ecosystems and make package managers interoperable. However, there is also an $N \times N$ problem of translating between ecosystem metadata

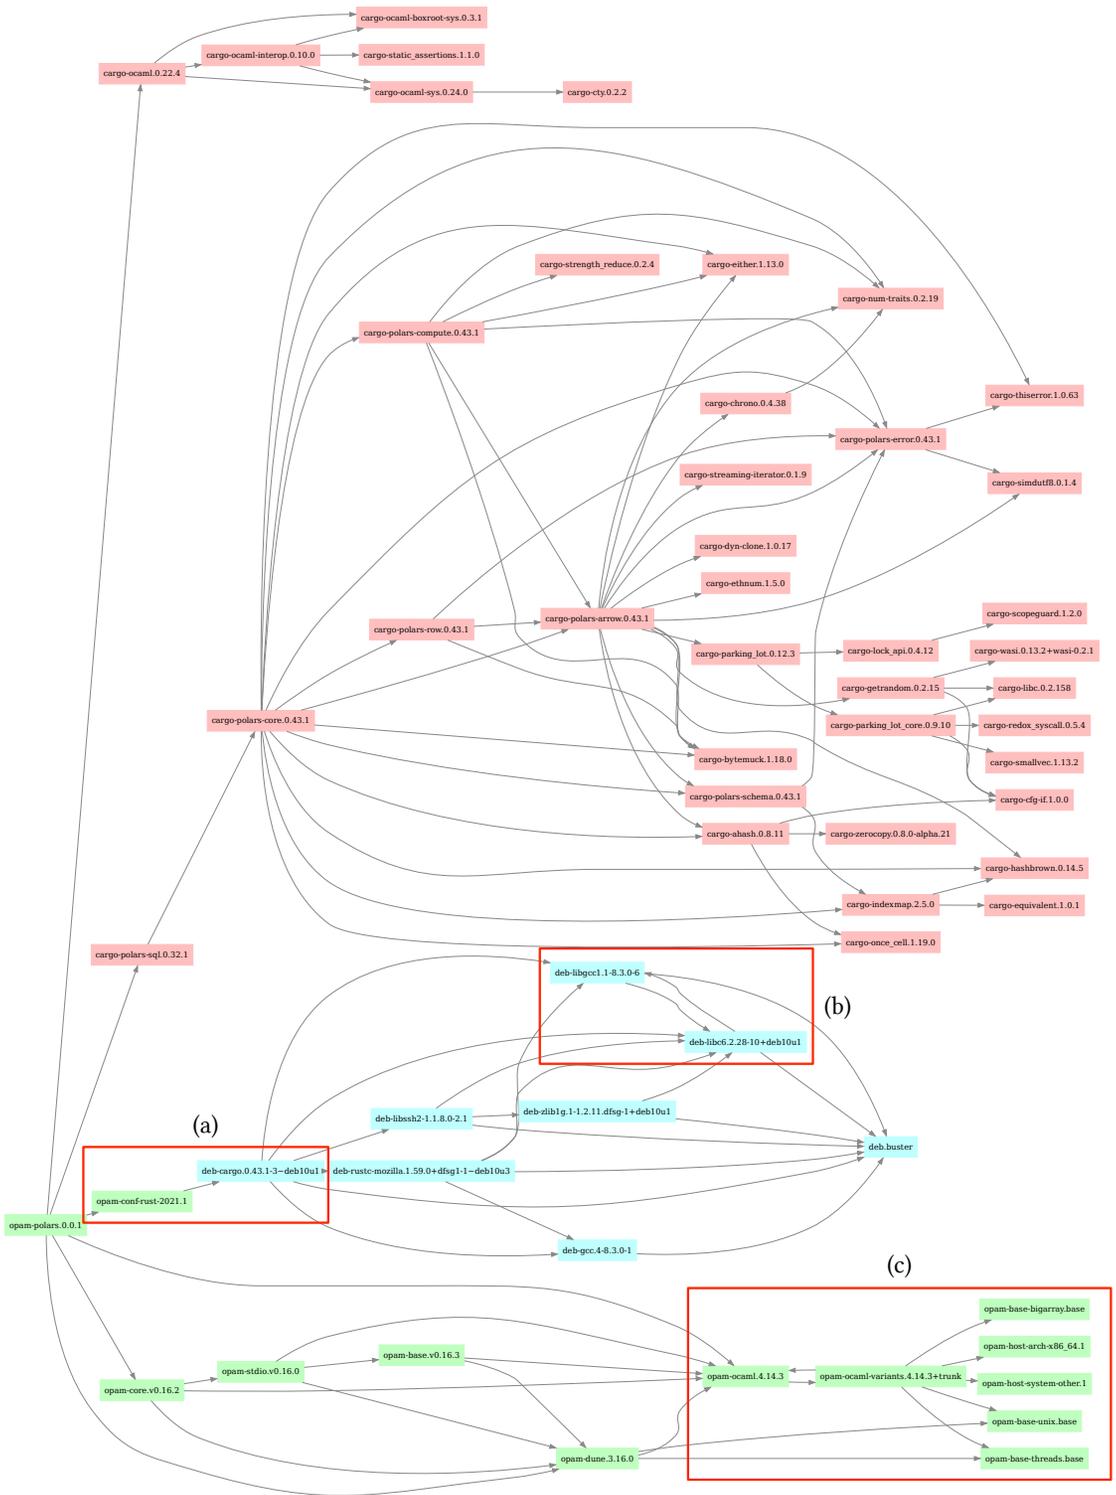

Fig. 11. A subgraph of the full cross-ecosystem resolved graph querying opam’s polars.1.0.0 library. (a) shows a Rust to Debian dependency, (b) shows a Debian cycle, (c) shows an OCaml post-cycle.

■ Cargo ■ Debian ■ Opam

bundles. This would allow the many millions of packages spread across ecosystems (Table 1) to be directly incorporated into other ecosystems. For example, Debian packages could be created directly from all the language-specific package managers that are binary compatible with the existing Debian packages, and without requiring the labour-intensive process of creating a Debian package for each language-specific package.

This translation process is easier for some package managers than others, and made significantly easier by the HyperRes formalism. For example, translating an opam file to a deb archive is quite feasible due to the simple archive format of Debian source packages. Others are harder, like the Nix package manager, but given an API into the Nix store the tools could create derivations *translated* from another ecosystem. Such metadata translations would allow the resolved graphs to all be translated to one target ecosystem, allowing for the deployment of packages using a single tool.

Package managers are often platform-specific, but this ‘protocol’ for package management would allow for package management systems specific to platforms, using technologies like namespaces on Linux and Jails on FreeBSD, still to interoperate. This enables a new generation of package managers using a common protocol that can be hyper-specialised to an operating system or environment.

6 RELATED WORK

SAT for Package Resolving. The core idea of using a formalism to aid with package versioning dates back to Opium [58] in 2007, which adapted Debian’s apt-get to use a SAT solver for dependency resolution. Opium showed that such resolving could be done efficiently, and later work on CUDF [56] specified a file format that could be used by specialised package resolvers. One such early resolver used answer-set programming [32], which also found use in high-performance computing software infrastructure for solving dependencies with support for a rich set of user-specified resolver preferences [30]. However, these systems did not halt the proliferation of package managers in the past decade, and the problem of cross-ecosystem dependencies has only grown worse in the intervening years.

Abate et al. noted in 2020 that while SAT-based dependency solving did find traction among some package manager implementations, the idea of using reusable components for version solving had not taken off [11]. In recent years, some of the larger package ecosystems such as NPM are under severe scaling pressure, and it is becoming increasingly important to revisit the question of how to reuse knowledge across ecosystems. For example, PacSolve’s MaxSMT based resolver is a drop-in replacement to NPM that reduced vulnerabilities in resolved packages and picked fresher and fewer dependencies [48]. Approximate solving has also been useful for package selection under bounded latency situations [36]. However, these systems are still tied to a single ecosystem, and HyperRes is our attempt to bridge this gap and provide a ‘babelfish’ for package management that will allow for the reuse of knowledge across ecosystems.

Open-source Ecosystems. There is an enormous and increasing amount of open-source software being published, and the problem of managing dependencies is only going to get worse. Software Heritage is building a universal archive of this source code [13], and HyperRes offers the chance to build a higher-level and cross-ecosystem semantic representation of these interdependencies.

Maintainers of some of the key distributions such as Debian (which form the basis for many other downstream products) are having to scale their automation in order to manage the ever-growing package set [18] and vulnerabilities [40]. The HyperRes approach of bringing common semantic meaning across language ecosystems should help reuse tooling that is currently language-specific to support the distribution maintainers such as those in Debian or CentOS. Being able to reason about large-scale dependencies is also important to alleviating the reproducibility crisis in scientific

computing [37], and HyperRes could (with sufficient tooling) support the longer-term availability of published scientific results.

Build Systems. Package management also has a close tie-in to build systems, which are equally surprisingly poorly-specified [44]. Build systems and package management systems are sometimes unified in newer toolchains (Table 1), but doing so makes it difficult to compose projects that span ecosystems (e.g. consider the difficulty of depending on a Rust library from OCaml code with just two package managers involved). Therefore, the HyperRes approach of specifying a formalism that can be implemented as a translation library across package ecosystems maintains the separation from the underlying build systems. In the long term, creating a composable formal theory of build systems and package managers [14] would let us combine cross-ecosystem codebases to conduct correctness testing across the vast amount of source code published [41]. It would also allow the use of fuzzing techniques on HyperRes to spot incorrect packaging specifications, which is a technique successfully applied to build systems [39].

Software Supply Chain Security. The increasing complexity of cross-ecosystem dependency chains puts pressure on the security of software supply chains, both on the choice of dependencies selected for a software project [15, 16, 59] but also in vulnerabilities in the many package managers available [21, 22]. Software Bill of Materials (SBOMs) manifests are being rapidly adopted [23] to specify the full set of versioned dependencies that go into a given application. However, the same problem of uneven quality across ecosystems applies here, with the JavaScript ecosystem being particularly unpredictable [51]. HyperRes could be used to generate SBOMs systematically, to reduce transitive trust dependencies across language and OS ecosystems [53], drop resource usage by debloating unnecessary packages [47], and reduce the latency of applying security updates in third party dependencies [52, 55].

Some popular languages, such as C++, have had surprisingly limited uptake of package management. Survey results [43] show that many of the features needed by users to adopt package management are reflected in the HyperRes formalism set, but users also require close integration with the system package manager — another new feature supported by HyperRes.

Human-in-the-loop Automation. LLMs are increasingly used for code generation tasks, and package management metadata is well-placed for automation here, with some early work showing promising results [27]. One future direction that HyperRes could go in is to support LLM-driven human-in-the-loop package management [33] via its concise and information-dense hypergraph representation. Similar work on automating Dockerfile repair [34] has shown promising results, and the same techniques could apply to simplifying the housekeeping of the many package manager metadata files in use today.

7 CONCLUSION

We have presented HyperRes, a formalism that finds commonality among the many diverse package managers in wide use for software development today. We have surveyed a representative set of package managers in use today and used HyperRes to translate individual packaging systems into our formalism, and then taken advantage of modern constraint solvers to answer versioning queries that span operating system and programming language ecosystems. And we have also shown a path to developing a ‘babelfish’ for package management that can use HyperRes to support the bidirectional translation of packages between ecosystems. This in turn will allow for the reuse of packaging knowledge across open-source ecosystems, and greatly simplify and secure the increasingly complex software supply chain in use today.
